# Cold-Water Immersion and Lower Limb Muscle Oxygen Consumption as Measured by Near-Infrared Spectroscopy in Trained Endurance Athletes

Ben Jones, PhD\*; Sally Waterworth, PhD\*; Jamie Tallent, PhD\*; Mike Rogerson, PhD\*; Chris Morton, MSc\*; Jason Moran, PhD\*; Rob Southall-Edwards, PhD†; Chris E. Cooper, PhD\*; Chris McManus, PhD\*

\*School of Sport, Rehabilitation and Exercise Sciences, University of Essex, Colchester, UK; †Essex County Council, Chelmsford, UK

**Context:** Cold-water immersion (CWI) has been reported to reduce tissue metabolism postimmersion, but physiological data are lacking regarding the muscle metabolic response to its application. Near-infrared spectroscopy (NIRS) is a noninvasive optical technique that can inform muscle hemodynamics and tissue metabolism.

**Objective:** To investigate the effects of CWI at 2 water temperatures (10 $\degree$ C and 15 $\degree$ C) on NIRS-calculated measurements of muscle oxygen consumption  $(mVO<sub>2</sub>)$ .

Design: Crossover study.

Setting: University sports rehabilitation center.

Patients or Other Participants: A total of 11 male National Collegiate Athletic Association Division II long-distance runners (age = 23.4  $\pm$  3.4 years, height = 1.8  $\pm$  0.1 m, mass = 68.8  $\pm$ 10.7 kg, mean adipose tissue thickness  $= 6.7 \pm 2.7$  mm).

**Intervention(s):** Cold-water immersion at  $10^{\circ}$ C and  $15^{\circ}$ C for 20 minutes.

**Main Outcome Measure(s):** We calculated  $mVO<sub>2</sub>$  preimmersion and postimmersion at water temperatures of  $10^{\circ}$ C and  $15^{\circ}$ C. Changes in tissue oxyhemoglobin (O2Hb), deoxyhemoglobin (HHb), total hemoglobin (tHb), hemoglobin difference (Hb<sub>diff</sub>), and tissue saturation index (TSI %) were measured during the 20-minute immersion at both temperatures.

**Results:** We observed a decrease in  $mVO<sub>2</sub>$  after immersion at both 10°C and 15°C ( $F_{1,9} = 27.7801$ ,  $P = .001$ ). During the 20-minute immersion at both temperatures, we noted a main effect of time for O<sub>2</sub>Hb ( $F_{3,27}$  = 14.227, P = .001), HHb ( $F_{3,27}$  = 5.749,  $P = .009$ , tHb ( $F_{3,27} = 24.786$ ,  $P = .001$ ), and Hb<sub>diff</sub> ( $F_{3,27} = 3.894$ ,  $P = .020$ ), in which values decreased over the course of immersion. Post hoc pairwise comparisons showed that these changes occurred within the final 5 minutes of immersion for tHb and  $O<sub>2</sub>$ Hb.

**Conclusions:** A 20-minute CWI at 10°C and 15°C led to a reduction in mVO<sub>2</sub>. This was greater after immersion at  $10^{\circ}$ C. The reduction in  $mVO<sub>2</sub>$  suggests a decrease in muscle metabolic activity (ie,  $O<sub>2</sub>$  use after CWI). Calculating mVO<sub>2</sub> via the NIRSocclusion technique may offer further insight into muscle metabolic responses beyond what is attainable from observing the NIRS primary signals.

Key Words: cryotherapy, optics, distance running, recovery

## Key Points

- Cold-water immersion at 10°C and 15°C for 20 minutes decreased muscle oxygen consumption (mVO<sub>2</sub>) as measured by near-infrared spectroscopy.
- The reduction in mVO<sub>2</sub> was greater after immersion at 10 $^{\circ}$ C.
- A threshold temperature and immersion duration at which  $mVO<sub>2</sub>$  decreases may exist.

old-water immersion ([C](#page-6-2)WI) is one of the most [c](#page-6-0)[om](#page-6-1)monly applied cooling modalities postexercise.<sup>1,2</sup> It is used to rapidly cool whole limbs and large muscle groups<sup>3</sup> to facilitate reductions in muscle blood flow (mBF) and muscle metabolism. Postexercise cooling is thought to limit the extent of secondary damage via temperature-induced reductions in tissue metabolism and microvascular blood flow to the damaged muscle.<sup>4[,5](#page-6-4)</sup> Indeed, reductions in skin, muscle, and conduit artery blood flow have been shown using a variety of measures, including laser doppler flowmetry, ultrasound, and near-infrared spectroscopy  $(NIRS)$ <sup>5[–](#page-6-4)8</sup> A noninvasive optical technique, NIRS is a valid tool for continuously monitoring changes in local muscle hemodynamics and muscle

oxygenation. In reviews, researchers have detailed the history and theory of the technique<sup>[9](#page-6-5)</sup> and applications in sport and health.<sup>10</sup> Changes ( $\Delta$ ) in NIRS-derived measures of total hemoglobin (tHb) and tissue saturation index (TSI %) have been used as a proxy for mBF and muscle metabolic activity, respectively,<sup>11[,12](#page-6-8)</sup> providing insight into the physiological effects of CWI.

A postexercise reduction in tHb is commonly observed during CWI, $^{7,8}$  $^{7,8}$  $^{7,8}$  and this finding is typically reported as a postimmersion reduction in local muscle blood volume (ie, tHb), explained as a reduction in mBF due to peripheral vasoconstriction. The TSI % response to CWI is less clear, with investigators reporting no change,<sup>7</sup> an increase (suggesting reduced

Figure 1. Illustration of the experimental protocol. Abbreviation: NIRS, near-infrared spectroscopy.

metabolic activity), $\delta$  or a decrease (suggesting increased metabolic activity). $13$ 

Collectively, the authors of these studies have demonstrated the ability of NIRS measurements to monitor local muscle hemodynamics and muscle oxygenation both during and after CWI. However, conflicting findings and interpretations of  $\Delta$ TSI % and thus muscle metabolic activity exist. To the best of our knowledge, all CWI studies using NIRS have been carried out postexercise, whereby any changes would be largely influenced by increased muscle and skin blood flow.<sup>[11](#page-6-7)</sup> These are confounders of NIRS measurement,<sup>[14](#page-6-12)</sup> which may have influenced previous interpretations. Furthermore, tHb and TSI % signals can provide only indirect and relative changes in local muscle blood volume and muscle oxygen  $(O_2)$  saturation, respectively. As such, they cannot be used to accurately quantify changes in either mBF or muscle  $O<sub>2</sub>$  consumption  $(mVO<sub>2</sub>)$ .<sup>10,[15](#page-6-13)</sup> To account for these concerns, a physiological intervention in the form of an arterial occlusion (AO), which manipulates blood flow entering and leaving the limb, can be implemented to enable quantification of  $mVO<sub>2</sub>$ .<sup>[16](#page-6-14)</sup> Furthermore, the application of CWI at rest (as opposed to postexercise) and the use of AO should remove the influence of skin blood flow<sup>9,[10](#page-6-6)</sup> and exercise hyperemia from the NIRS measurement, offering a more robust measurement approach.

To date, no specific guidelines exist regarding the optimal application of CWI to augment recovery from exercise. Durations and temperatures of CWI that have generally shown positive effects on recovery are between 10 and 20 minutes and  $10^{\circ}$ C and  $15^{\circ}$ C, respectively,<sup>17</sup> but few researchers have assessed the influence of different CWI protocols (eg, temperatures and durations) on physiological measures of muscle metabolism. Therefore, the purpose of our study was to evaluate the effects of CWI at 2 water temperatures ( $10^{\circ}$ C and  $15^{\circ}$ C) on NIRS-calculated measurement of  $mVO<sub>2</sub>$ . Given that colder water temperatures lead to greater reductions in tissue tempera-ture<sup>5[,7](#page-6-9)</sup> and that the premise of CWI is to reduce the metabolic rate of tissue,<sup>18</sup> we hypothesized that the application of CWI at 10 $\rm ^{o}C$  but not 15 $\rm ^{o}C$  would reduce mVO<sub>2</sub> postimmersion.

# METHODS

# **Participants**

Ten men (age = 23.4  $\pm$  3.4 years, height = 1.8  $\pm$  0.1 m, mass  $= 68.8 \pm 10.7$  kg) volunteered for this study. Mean adipose tissue thickness beneath the NIRS device was 6.7  $\pm$ 2.7 mm. All participants were long-distance runners competing for the same National Collegiate Athletic Association Division II team. They refrained from consuming caffeine and alcohol for 48 hours before each testing session. All individuals provided written informed consent, and the study was approved by the University of Essex research subcommittee.

# Experimental Design

A randomized crossover design was implemented to assess the influence of CWI on  $mVO<sub>2</sub>$ . Each person was required to participate in 2 testing sessions, separated by at least 24 hours. Participants attended the university sports therapy center at the same time of day, where they were randomly assigned to 1 of 2 recovery interventions,  $10^{\circ}$ C or  $15^{\circ}$ C CWI, for 20 minutes. Before and after CWI, AO of the leg undergoing NIRS assessment was performed. An overview of the experimental protocol is shown in Figure 1.

## Preparation

The NIRS device was placed on the midportion of the medial gastrocnemius muscle belly. To ensure accuracy of repeat device placement, we drew an outline of the device on the limb using a surgical marker pen. Participants were instructed to maintain the outline during the testing period. Limb skinfold thickness was measured at the site of device attachment using Harpenden skinfold calipers (Baty International). The limb undergoing assessment was randomly assigned.

# The CWI Protocol

Participants wore shorts and sat in an upright position in an immersion bath (model S-85-S; Whitehall Manufacturing), which was filled with water to the level of the navel. Water temperature was monitored using a digital aquarium thermometer, maintained within  $\pm 0.3^{\circ}$ C of 10°C or 15°C, and stirred every 2 minutes using an inbuilt whirlpool machine. Individuals were instructed to keep as still as possible and not activate their lower limb muscles during immersion. After immersion, they exited the recovery bath and quickly towel dried before transitioning to the post-CWI occlusion. This transition period took  $\leq$ 120 seconds.

# Occlusion Protocol

Arterial occlusions were performed for 5 minutes at a pressure of 250 mm  $Hg<sup>19</sup>$  $Hg<sup>19</sup>$  $Hg<sup>19</sup>$  before (baseline) and after CWI. A pressure cuff (model SC10D; DE Hokanson, Inc) was attached to the participant's limb just above the knee joint and inflated to the corresponding pressure. The occlusion protocol was identical for both testing sessions, whereby participants lay supine on a therapy plinth next to the CWI bath. The protocol consisted of 1 AO (baseline), followed by a 5-minute recovery before transitioning to CWI. Post-CWI, each person returned to the therapy plinth, and the procedure was repeated.

## The NIRS Measurements

A portable NIRS device (model PortaMon; Artinis Medical Systems BV) was fixed with black adhesive tape over

the marked measurement site to prevent signal contamination from external light sources. The device was made waterproof as previously described.<sup>20</sup> The same researcher (R.S.E.) attached each device and applied the adhesive tape for all testing procedures. To account for the external pressure applied to the muscle belly, we used a standardized approach.<sup>21</sup> The PortaMon is a dual-wavelength, continuous-wave system that simultaneously uses the modified Beer-Lambert law and spatially resolved spectroscopy methods. Changes in tissue oxyhemoglobin  $(O_2Hb)$ , deoxyhemoglobin (HHb), and tHb were measured using the difference in absorption characteristics of wavelengths at  $760$  and  $850$  nm. Values for O<sub>2</sub>Hb, HHb, and tHb are reported as a concentration change from baseline (30 second averaging before each test with participants in the supine position) in micromolar units, using a differential path length factor of 4.0. Hemoglobin difference (Hb $_{diff}$ ) was calculated as follows:  $[Hb_{diff}] = [O<sub>2</sub>Hb] - [HHb]$ . The TSI % was expressed as a percentage and calculated as follows:  $[O_2Hb]/([O_2Hb] + [HHb]) \times 100$ . It is independent of the NIR photon path length in muscle tissue and was calculated using the spatially resolved spectroscopy method. Chromophore concentrations were detected using the farthest lightemitting diode (40 mm). Data were collected offline at a sampling rate of 10 Hz.

#### Muscle Oxygen Consumption

We calculated  $mVO<sub>2</sub>$  by evaluating the linear decrease in  $([Hb<sub>diff</sub>] = [O<sub>2</sub>Hb] - [HHb]),$  according to [Equation 1.](#page-2-0) The linear decrease in  $Hb_{diff}$  was calculated between 30 and 150 seconds as described earlier.<sup>[22](#page-7-5)</sup> Concentration changes of Hb<sub>diff</sub> were expressed in micromolars per second and converted to milliliters  $O_2$  per minute per 100 g tissue. A value of 1.04 kg·L<sup>-1</sup> was used for muscle density.<sup>16</sup> The mVO<sub>2</sub> measurement demonstrated good reliability during rest and dynamic exercise, with various estimates of reproducibility shown (coefficient of variation  $[CV] =$  about 6% to 20%).<sup>23</sup>

<span id="page-2-0"></span>
$$
mVO_2=\frac{\left(\left(\left(\frac{\Delta Hb_{diff}}{2}\times 60\right)\div(10\times 1.04)\right)\times 4\right)\times 22.4}{1000}\qquad (1)
$$

#### Statistical Analysis

All results are reported as mean  $\pm$  SD. Normality and outliers were verified using the Shapiro-Wilk test and by observing the normality plots and residual plots. Preimmersion data of participant 3 were identified as outliers for both temperatures. We calculated imputed estimates using the fully conditional specification method to account for this.<sup>[24](#page-7-7)</sup> Mean values for O<sub>2</sub>Hb, HHb, tHb, Hb<sub>diff</sub>, and TSI % were determined for the 20-minute CWI and for 5-minute segments. Two-way repeated-measures analysis of variance was conducted for all NIRS measures obtained in each 5 minute segment of immersion; within-participant variables were time (5, 10, 15, and 20 minutes) and temperature  $(10^{\circ}$ C and 15<sup>°</sup>C). When a main effect of time was present, post hoc analysis was performed using a Bonferroni correction factor. Effect sizes were calculated using partial eta squared  $(\eta_p^2)$  $(\eta_p^2)$  $(\eta_p^2)$ . Values were interpreted as *small*  $(\eta_p^2 = 0.01)$ , *medium*  $(\eta_p^2 = 0.06)$  $(\eta_p^2 = 0.06)$  $(\eta_p^2 = 0.06)$ , or *large*  $(\eta_p^2 = 0.14)$  effect sizes. Two-way repeated-measures analysis of variance was computed for  $mVO<sub>2</sub>$ ; within-participant variables were time (pre- and post-CWI) and temperature ( $10^{\circ}$ C and  $15^{\circ}$ C). Further post hoc analysis was conducted on  $mVO<sub>2</sub>$  values for pre- and post-CWI at  $10^{\circ}$ C and  $15^{\circ}$ C. We set the level of significance at  $P < .05$ . All statistical analysis was performed using SPSS (version 25; IBM Corp).

## RESULTS

Representative examples of the  $O_2Hb$ , HHb, tHb, and Hb $_{diff}$ traces and TSI % during the experimental protocol  $(10^{\circ}C)$  are displayed in [Figure 2A and B](#page-3-0), respectively. A similar response was seen in the group data.

Pre- and post-AO elicited similar responses. At the onset of AO, a steady and progressive decrease in  $O<sub>2</sub>$ Hb concomitant with an increase in HHb concentration was present throughout the 5-minute occlusion, which reflects depletion of local  $O<sub>2</sub>$  stores in the static compartment of blood. A more rapid decrease in  $Hb_{diff}$  concentration occurred at the onset of AO. The Hb<sub>diff</sub> represents the difference in concentration between  $O<sub>2</sub>$ Hb and HHb and therefore provides the extent of desaturation taking place during occlusion. The TSI % signal largely followed the same trend as the O<sub>2</sub>Hb and Hb<sub>diff</sub>, with large decreases in saturation during both pre- and post-AO and minimal change during the 20-minute immersion period. The NIRS trace responses were similar for  $10^{\circ}$ C and  $15^{\circ}$ C, with no main effects ( $P > .05$ ) across all NIRS measures for temperature or temperature  $\times$  time interactions. A main effect of time was noted for O<sub>[2](#page-6-1)</sub>Hb  $(F_{3,27} = 14.227, P = .001, \eta_p^2 = .001, \eta_p^2 = .001$ 0.613), HHb  $(F_{3,27} = 5.749, P = .009, \eta_p^2 = 0.344)$  $(F_{3,27} = 5.749, P = .009, \eta_p^2 = 0.344)$  $(F_{3,27} = 5.749, P = .009, \eta_p^2 = 0.344)$ , tHb  $(F_{3,27} = 24.786, P = .001, \eta_p^2 = 0.734)$  $(F_{3,27} = 24.786, P = .001, \eta_p^2 = 0.734)$  $(F_{3,27} = 24.786, P = .001, \eta_p^2 = 0.734)$ , and Hb<sub>diff</sub>  $(F_{3,27} = 10^{-10} \text{ m/s}^2)$ 3.894,  $P = .020$  $P = .020$  $P = .020$ ,  $\eta_p^2 = 0.302$ ) during the immersion, whereby they decreased over the 20-minute immersion period. No effect of time was evident for TSI % ( $F_{3,27} = 2.859$ ,  $P = .056$ ,  $\eta_p^2 = 0.241$  $\eta_p^2 = 0.241$  $\eta_p^2 = 0.241$ .

A nadir or flattening was reached in the  $O<sub>2</sub>Hb$ , HHb, and  $Hb_{diff}$  signals during AO, indicating complete desaturation [\(Figure 3\)](#page-4-0). The overlapped  $O<sub>2</sub>Hb$ , HHb, tHb, and Hb<sub>diff</sub> signals pre- and post-AO for the 10°C immersion trial are shown in [Figure 4](#page-4-0). The rate of decrease in  $O<sub>2</sub>Hb$  ([A] in [Figure 3\)](#page-4-0) and  $Hb_{diff}$  ([D] in [Figure 3\)](#page-4-0) concentrations was noticeably slower over the 5-minute occlusion post-AO (the slope value for the line, as calculated using linear regression, confirmed this). Similar end values were achieved. This may reflect a slower depletion of local  $O_2$  stores during the post-AO. After cuff release of both AOs, rapid resaturation occurred and was seen as an increase in  $O_2Hb$  ([A] in [Figure 3](#page-4-0)) and  $Hb_{diff}$  ([D] in [Figure 3\)](#page-4-0) and a concomitant decrease in HHb ([B] in [Figure 3](#page-4-0)), which also displayed an attenuated response during post-AO. Restoration of all signals was demonstrated after 1 to 2 minutes.

Post hoc analysis revealed reductions in the last 5-minute period of immersion (15–20 minutes) versus earlier periods of immersion for O<sub>2</sub>Hb (10–15 minutes,  $P = .005$ ; 5–10 minutes,  $P = .03$ ; and 0–5 minutes  $P = .007$ ) and tHb (10–15 minutes,  $P = .001$ ; 5–10 minutes,  $P = .002$ ; and 0–5 minutes,  $P = .001$ ). In addition, we observed reductions in tHb at 10 to 15 minutes (5–10 minutes,  $P = .040$ ; 0–5 minutes,  $P = .008$ ) and 5 to 10 minutes (0–5 minutes,  $P = .02$ ) compared with earlier periods of immersion. The reductions in  $O<sub>2</sub>Hb$  and tHb represented a change of about 2 to 4  $\mu$ M [\(Table\)](#page-5-0).

A main effect of time for  $mVO<sub>2</sub>$  pre- and post-CWI for both temperatures  $(F_{1,9} = 27.7801, P = .001, \eta_p^2 = 0.755)$  $(F_{1,9} = 27.7801, P = .001, \eta_p^2 = 0.755)$  $(F_{1,9} = 27.7801, P = .001, \eta_p^2 = 0.755)$ was observed:  $\text{mVO}_2$  decreased as a result of CWI [\(Figure 5](#page-5-1)). We did not find a main effect of temperature  $(F_{1,9} = 1.996,$  $P = .19$ ,  $\eta_p^2 = 0.181$  $\eta_p^2 = 0.181$  $\eta_p^2 = 0.181$ ) despite the large effect size. We

<span id="page-3-0"></span>

Figure 2. Oxyhemoglobin (O<sub>2</sub>Hb), deoxyhemoglobin (HHb), total hemoglobin (tHb), hemoglobin difference (Hb<sub>diff</sub>), and tissue saturation index (TSI %) traces from a representative participant during the experimental protocol. Solid black lines indicate the time when arterial occlusions (AOs) took place. In the top panel, A–D denote  $O_2Hb$ , HHb, tHb, and Hbdiff traces, respectively. Data for participant 3 were not used for the representative example because the individual's preimmersion data were identified as outliers.

observed a temperature  $\times$  time interaction ( $F_{1,13} = 13.302$ ,  $P = 0.006$ ,  $\eta_p^2 = 0.592$  $\eta_p^2 = 0.592$  $\eta_p^2 = 0.592$ ), with a large effect size.

The main effect for time can be seen in the decrease in  $\text{mVO}_2$ from preimmersion to postimmersion ( $P = .001$ ; [Figure 5\)](#page-5-1). [Figure 5](#page-5-1) also shows a decrease in both temperature conditions, and this decrease was bigger postimmersion at  $10^{\circ}$ C than 15 $^{\circ}$ C. The slope of the line for preimmersion versus postimmersion  $mVO<sub>2</sub>$  was clearly steeper at 10<sup>o</sup>C than at 15<sup>o</sup>C, as implied by the effect size and difference of the time  $\times$  temperature interaction effect ( $P = .006$ ). The large main effect for time describes the decline in  $mVO<sub>2</sub>$  from preimmersion to postimmersion at both temperatures (ie, the interventions were effective across both temperatures). The magnitude of the interaction effect illustrates the difference that temperature had on the preimmersion to postimmersion decline between conditions. Together, the large main effect for time and large interaction effect showed that immersion at  $10^{\circ}$ C to 15°C reduced mVO<sub>2</sub> and immersion at 10°C resulted in a larger reduction in  $mVO<sub>2</sub>$  than immersion at 15°C.

## **DISCUSSION**

We investigated the effect of 20-minute CWI at  $10^{\circ}$ C and  $15^{\circ}$ C on gastrocnemius mVO<sub>2</sub> measured by NIRS. To address

<span id="page-4-0"></span>

Figure 3. A representative example of oxyhemoglobin (O<sub>2</sub>Hb), deoxyhemoglobin (HHb), total hemoglobin (tHb), and hemoglobin difference (Hb<sub>diff</sub>) traces during 5-minute arterial occlusions (AOs) and after cuff release (AO end). The experimental approach used to calculate muscle oxygen consumption has been annotated on the Hb<sub>diff</sub> trace. (A) through (D) denote O<sub>2</sub>Hb, HHb, tHb, and Hb<sub>diff</sub> traces, respectively.

the limitations of previous research, we combined NIRS measures of hemodynamic response with the AO procedure to more robustly quantify  $mVO<sub>2</sub>$  post-CWI. The main findings were that CWI decreased mVO<sub>2</sub> after 20-minute immersion at 10 $\rm ^{o}C$  and 15 $\rm ^{o}C$ . A greater reduction in mVO<sub>2</sub> was seen at the colder temperature  $(10^{\circ}C)$ . These results disagree with our hypothesis that CWI would cause a postimmersion reduction in mVO<sub>2</sub> at 10<sup>o</sup>C but not 15<sup>o</sup>C. However, the finding that a colder immersion temperature led to a larger reduction in  $mVO<sub>2</sub>$  was in line with our premise.

## Muscle Oxygen Consumption

Muscle oxygen consumption was reduced after 20-minute CWI at  $10^{\circ}$ C and  $15^{\circ}$ C, indicating the interventions were effective across both temperatures. The reduction was greater

Figure 4. Data for the 10°C immersion group of the oxyhemoglobin (O<sub>2</sub>Hb), deoxyhemoglobin (HHb), total hemoglobin (tHb), and hemoglobin difference (Hb<sub>diff</sub>) traces during 5-minute arterial occlusions (AOs) and after cuff release (AO end), with the traces for baseline and post-AO overlapped for visual comparison. Data have been time aligned and normalized for comparison. A, O<sub>2</sub>Hb. B, HHb. C, tHb. D, Hb<sub>diff</sub>. (a) indicates before cold-water immersion; (b), after cold-water immersion.

at  $10^{\circ}$ C. This outcome suggests that CWI at  $10^{\circ}$ C and  $15^{\circ}$ C reduced  $O_2$  use in the muscle, which was consistent with the mechanism of recovery by which CWI is proposed to prevent inflammation and secondary hypoxic injury.<sup>25,[26](#page-7-9)</sup> To accurately quantify mVO2, we performed AOs at baseline and post-CWI. These AOs temporarily arrest blood flow, creating a "static" compartment of blood in the muscle in which the linear decrease in  $O_2Hb$  or  $Hb_{diff}$  directly reflects the rate at which the preexisting  $O_2$  store in the blood compartment is consumed.<sup>16</sup> As such, this method has the advantage of quantifying the  $O_2$  use element of the TSI % measurement while eliminating the influence of further  $O_2$  supply. Researchers have proposed that the reduced tissue metabolism associated with CWI is mediated through reductions in tissue tempera-ture.<sup>5,[27](#page-7-10)</sup> While we did not measure tissue temperature, a reduction likely did occur, as authors using similar CWI protocols observed reductions in tissue temperature during and after immersion.<sup>5[,27](#page-7-10)</sup> A 24% reduction in post-CWI mVO<sub>2</sub> was seen after immersion at 10 $\degree$ C, with a 13% reduction at 15 $\degree$ C, reflecting the influence of the  $5^{\circ}$ C temperature reduction on  $mVO<sub>2</sub>$ . Changes in muscle blood volume (discussed later) also occurred with CWI at both  $10^{\circ}$ C and  $15^{\circ}$ C but only during the last 5 minutes of immersion. Therefore, an interaction between temperature and duration should be considered when interpreting muscle metabolic responses. Indeed, the greater reduction in  $mVO<sub>2</sub>$  at 10<sup>o</sup>C is an interesting finding and suggests a possible threshold temperature at which reductions in tissue metabolism occur and below which colder temperatures lead to greater reductions in metabolism. In fact, Wakabayashi et al<sup>[28](#page-7-11)</sup> observed the effect of decreasing muscle forearm temperature (via cooling pads) on NIRS-derived  $mVO<sub>2</sub>$ 

Figure 5. Muscle oxygen consumption measured at each time, mean  $\pm$  SD (n = 10).  $\Delta P$  = .001.  $\Delta P$  = .006.

and reported higher  $mVO<sub>2</sub>$  values at higher tissue temperatures. Yet focusing solely on immersion temperature is potentially misleading, as shown by the large interaction effect, because both time and temperature play roles in reducing tissue metabolism. The benefit at colder immersion temperatures likely relates to efficiency (ie, reduced immersion periods). However, warmer immersions for longer durations could result in the same reduction in metabolism. To the best of our knowledge, we are the first to use the AO technique with NIRS measurements to establish  $mVO<sub>2</sub>$  changes in response to different CWI temperatures. Our findings of reduced  $mVO<sub>2</sub>$  support earlier reports of reduced muscle metabolic activity[.7,](#page-6-9)[8](#page-6-10) Although an accurate quantification of muscle metabolic activity is certainly useful and extends prior results, the threshold or extent of reduced muscle metabolic activity required to aid recovery is still unknown. An optimal reduction threshold may exist, but any quantification is outside the constraints of our study.

#### Muscle Blood Volume

The NIRS-derived measurements of muscle blood volume (ie, tHb) have shown blood volume reductions durin[g7](#page-6-9)[,8](#page-6-10) and after postexercise CWI,<sup>7,[29](#page-7-12)</sup> with  $\Delta$ tHb used as an indirect and proxy measure of mBF. Collectively, previous investiga-tors<sup>6,[7](#page-6-9)[,30](#page-7-13)</sup> reported decreases in mBF during and after CWI. We saw an approximately  $4-\mu M$  reduction in tHb during 20minute CWI. Specifically, tHb was lower at 15 to 20 minutes during immersion compared with all other measured points, and the reduction in tHb was similar at both temperatures  $(10^{\circ}$ C and 15<sup>o</sup>C). More substantial decreases in tHb (approximately 20  $\mu$ M) have been noted over a 20-minute recovery period incorporating three 4-minute CWIs.<sup>31</sup> The different experimental design might be a reason for the disparate findings. Our participants performed CWI in a rested rather than immediate postexercise state, which may more accurately typify the extent of tHb change. Large increases in muscle and skin blood flow are seen postexercise due to exercise hyperemia. As such, a reduction in tHb relative to postexercise values occurs during and after CWI.[7](#page-6-9),[8](#page-6-10) Given that our participants did not exercise before CWI, the change in tHb would be expected to be smaller and provide a greater indication of blood volume changes seen when using CWI at 24 or 48 hours postexercise. During our CWI protocol, peak changes in tHb occurred within the last 5 minutes of immersion (15 to 20 minutes), with minimal changes observed earlier. Furthermore, the  $5^{\circ}$ C difference in immersion temperature did not influence the magnitude of tHb reduction. Our results, therefore, suggested that a small reduction in muscle blood volume (tHb) can be achieved in either  $10^{\circ}$ C or  $15^{\circ}$ C water after at least 15 minutes of immersion. These outcomes may have implications for selecting immersion durations, which currently range from 30 seconds to 30 minutes.<sup>[17](#page-7-0)</sup>

## Tissue Saturation Index

Authors of a small number of studies have used the TSI  $%$  response during and after CWI, with  $\Delta$ TSI % considered a proxy for changes in muscle metabolic activity[.7,](#page-6-9)[8,](#page-6-10)[13](#page-6-11)[,29](#page-7-12) We identified no changes in TSI % during the 20-minute CWI and marginal reductions in tHb at the end of immersion. No change in TSI %, despite a small reduction in local muscle blood volume (tHb), tentatively suggests decreased  $O_2$  use during this period, possibly reflecting a reduction in muscle metabolic activity. This finding and interpretation have been reported previously.<sup>8</sup> Other researchers<sup>7</sup> detected no change in TSI % values during CWI despite a reduction in tHb, which the authors interpreted as a decrease in  $O_2$  use because  $\Delta$ tHb is considered a proxy for mBF. However, these and other interpretations should be viewed with caution, as the TSI % measurement is a combination of muscle  $O_2$  supply and use, and thus inferences regarding use cannot be made with any certainty.

## Limitations

This study had several limitations. First, the portable NIRS device measures only a small  $(2-6 \text{ cm}^3)$  volume of muscle tissue. The values calculated for  $mVO<sub>2</sub>$  are assumed to represent the entire muscle, but given the restricted coverage of the gastrocnemius and its heterogeneity of fiber type and muscle metabolism,<sup>[32](#page-7-15)</sup> the changes likely did not represent the entire muscle. To obtain representative estimations, multisite  $mVO<sub>2</sub>$ measurements should be assessed. Second, skin blood flow can influence the NIRS  $(O<sub>2</sub>Hb$  and tHb) signals. For example, during whole-body heating, elevated skin blood flow influenced the NIRS signal, $14$  and it has been [wel](#page-6-4)l documented that cooling reduced cutaneous blood flow.5–<sup>7</sup> However, the effects of cooling on the NIRS signal have not been fully established. Our measurements of  $mVO<sub>2</sub>$  used the Hb<sub>diff</sub> signal, which is less influenced by skin blood flow and use of AO, which creates a closed loop system, to remove the influence of skin blood flow. Finally, the study sample was exclusively male and comprised well-trained long-distance runners; therefore, extrapolation to female and other sporting populations requires further research.

## **CONCLUSIONS**

We demonstrated that the NIRS-occlusion approach can detect changes in  $mVO<sub>2</sub>$  pre- and post-CWI and could provide future investigators with a simple tool to assess muscle metabolic activity. Although our results demonstrated that CWI influenced  $mVO<sub>2</sub>$ , the significance of a reduction due to CWI is yet to be established. A key finding was that  $mVO<sub>2</sub>$ decreased CWI at both temperatures after 20 minutes of immersion. This reduction was most pronounced after the colder immersion temperature. This indicated that colder immersion temperatures elicited a greater decrease in muscle metabolic activity.

The role of  $mVO<sub>2</sub>$  in postexercise recovery protocols must be established before the optimal immersion time or temperature for CWI can be determined. Indeed, the application of CWI as a recovery tool is still controversial, with evidence to suggest its regular use can ameliorate traininginduced changes after resistance training, with more beneficial findings associated with endurance-based training.<sup>[2](#page-6-1)</sup> The NIRS-occlusion technique may offer further insight into muscle metabolic responses, beyond what is attainable from the NIRS primary signals.

# ACKNOWLEDGMENTS

We thank the participants for taking part in the study.
